Exogenous Expression of Human Protamine 1 (hPrm1) Remodels Fibroblast Nuclei into Spermatid-like Structures

Authors
Domenico Iuso, Marta Czernik, Paola Toschi, ..., Saadi Khochbin, Grazyna Ewa Ptak, Pasqualino Loi

In Brief
Iuso et al. find that exogenous expression of human protamine 1 remodels interphase fibroblast nuclei into spermatid-like structures. The process is reversible upon nuclear transfer into enucleated oocytes. This finding could be exploited as a simplified model for investigating protamine-induced genome compaction and may also boost somatic cell nuclear transfer efficiency.

Highlights
- In vitro protaminization of somatic cell nuclei
- Conversion of interphase somatic nuclei into “spermatid-like” structures
- Protaminization of somatic nuclei that is reversed upon injection into enucleated oocytes
- A simplified model of nuclear remodeling and reprogramming in vitro
Exogenous Expression of Human Protamine 1 (hPTrm1) Remodels Fibroblast Nuclei into Spermatid-like Structures

SUMMARY

Protamines confer a compact structure to the genome of male gametes. Here, we find that somatic cells can be remodeled by transient expression of protamine 1 (PTrm1). Ectopically expressed PTrm1 forms scattered foci in the nuclei of fibroblasts, which coalesce into spermatid-like structures, concomitant with a loss of histones and a reprogramming barrier, H3 lysine 9 methylation. Protaminized nuclei injected into enucleated oocytes efficiently underwent protamine to maternal histone TH2B exchange and developed into normal blastocyst stage embryos in vitro. Altogether, our findings present a model to study male-specific chromatin remodeling, which can be exploited for the improvement of somatic cell nuclear transfer.

INTRODUCTION

Spermatogenesis is conserved from flies to mammals. Postmeiotic spermatocytes undergo a radical nuclear and cytoplasmic reorganization. Nuclear remodeling relies on a timely translation of stabilized mRNA transcribed at the round spermatid stage (Brock et al., 1980). The first transcripts are testis-specific core and linker histone variants (Gaucher et al., 2010; Kota and Feil 2010). Testis-specific histones have a lower affinity for DNA than somatic ones (Gaucher et al., 2010; Rousseaux and Khochbin, 2015; Morinieri et al., 2009) further destabilizes the nucleosome. Subsequently, acetylated histones are recognized by bromodomain testis-specific proteins (Brdt) (Pivot-Pajot et al., 2003; Gaucher et al., 2012), proteins that prepare the ground for the incorporation of transition proteins (TPs). TPs cooperate with topoisomerases to relieve torsional stress (Singh and Rao, 1988) and with DNA repairing enzymes (Akama et al., 1999). The substitution of TPs with protamine (Prm) completes nuclear remodeling, conferring a toroid structure to DNA and the unique shape of male gametes (Miller et al., 2010). Upon fertilization, remodeling is completely reversed. Paternal chromosomes rapidly lose Prm and testis-specific histones (van der Heijden et al., 2005; Wu et al., 2008; Loppin et al., 2005) and regain a nucleosomal organization built upon maternally provided histones.

When, instead, a somatic cell is used to “fertilize” an oocyte, as in somatic cell nuclear transfer (SCNT; Wilmut et al., 1997), the nucleosome organization of the chromatin is only occasionally reversed by the oocyte, often leading to developmental failure (Loi et al., 2013).

The current study set out to explore the possibility of conferring a somatic cell nucleus with a Prm-based toroid organization. Here, we demonstrate that the nuclei of adult somatic cells undergo a dramatic chromatin reorganization following the induced expression of the PTrm1 gene, transforming the nuclei into “spermatid-like” structures. The Prm-induced nuclear remodeling is reversible upon nuclear transfer (NT) of protaminized cells into enucleated oocytes, and the resulting embryos develop normally in vitro.

RESULTS

Spermatid-Specific Stepwise Chromatin Remodeling Does Not Function in Somatic Cells

Our first approach to remodel somatic cell nuclei was to induce the co-sequential and sequential expression of four main testis-specific genes in primary cultures of sheep fibroblasts, with the aim to repeat the nuclear remodeling occurring in spermatids. To this end, expression vectors for the bromodomain testis-specific (Brdt-GFP tag), TPs I and II (HA tag), and protamine 1 (Prm1-red variant of GFP tag) were generated and transfected into the fibroblasts. However, our attempts to induce chromatin remodeling of somatic cells following either a co-stepwise or a stepwise transfection of all four expression vectors failed.
The nuclear reorganization in spermatids relies on a hierarchic translation of synthetized mRNA, and each of the protein prepares the ground for the next one (Barckmann et al., 2013), a scenario we failed to repeat in cultured somatic cells. There are, however, exceptions to the canonical nucleosome disassembly pathway during spermatogenesis. In the male germline of the cephalopod *Sepia officinalis*, for instance, histones are replaced directly by Prm-like proteins (Martínez-Soler et al., 2007). Hence, we attempted to induce a direct nuclear remodeling in somatic cells through the transient expression of Prm. We selected Prm1 because ram spermatozoa contain Prm1 only and because Prm1 is synthetized as a mature protein with no further processing (de Mateo et al., 2011).

**Direct Incorporation of Prm1 into Somatic Chromatin**

We transfected sheep adult fibroblasts (SAFs) with pPrm1-RFP, WT Prm1, and RFP tag-only vectors using a lipofectamine transfection kit. Transfected cells approached 40% in all three groups. Expression of mRNA and protein Prm1 was confirmed by RT-PCR, by western blotting, and by tracking the RFP-tag (Figures 1, S1A, and S1B). Prm1-RFP co-localized with nuclei stained by Hoechst (Figure 1), whereas in control, i.e., pRFP transfected fibroblasts, the red signal was diffused in the cytoplasm and nucleus (Figure 1). Fibroblasts transfected with WT Prm1 showed nuclear reorganization similar to that detected in pPrm1-RFP transfected ones (Figures 1 and S2). At 40- to 48-hr post-transfection/trichostatin A (TSA) treatment, 93.3% of Prm1-cells did uptake Prm in nuclei, and 83.3% of Prm1-positive cells completely changed nuclear morphology (Table 1).

**Prm1 Binds to DNA**

Prm1 contains numerous cysteine residues that might form intra-Prm/inter-Prm disulfide cross-links (Balhorn et al., 1992). To exclude nuclear Prm1 polymerization, chromatin immunoprecipitation (ChiP)-seq assay was carried on of sorted Prm1-positive cells. The ChiP-seq assay confirmed the effective binding of Prm1 to DNA at 42 DNA binding sites on 10 of 27 chromosomes, as early as 16-hr post-pPrm1 transfection (Figure 1J; Table S1).

**Protamminization of Somatic Cells’ Nuclei Is Not Cell Cycle Dependent**

Cell-cycle analysis by cytofluorimetry of transfected cells revealed that Prm1 was incorporated in all cell-cycle stages (72.6% G1, 4.4% S, 23% G2 stage) (Table S2). Moreover, fibroblasts forced to enter G0 (by serum starvation) were transfected with pPrm1-RFP, and even in this case, Prm1 incorporation and chromatin compaction took place (Table 1). Thus, Prm incorporation on DNA is cell cycle independent. A likely mechanism for Prm1 deposition on chromatin might be the conformational changes that nucleosomes undergo as a result of chromatin remodeling enzymes or thermal fluctuations (Chereji and Morozov, 2015). These nucleosomal dynamics make available free stretches of 11 bp between the dyads, enough for Prm1 docking on DNA (Zhang et al., 1996). The low-off rates of Prm1 (Brewer et al., 2003) might facilitate the prolonged condensation of DNA even after transient Prm1 expression. To indirectly test this hypothesis, we transfected GFP-H2B fibroblasts with pPrm1-RFP. A histone-to-Prm exchange was observed in GFP-H2B (red) nuclei (Figure 1K). Unequivocally, the red fluorescent signal of Prm replaced the green H2B, confirming the over competition of Prm on histones (Figure 1K). Furthermore, we observed that the Prm replaced the histone H3 trimethylated on lysine 9 (H3K9me3), a critical epigenetic barrier of SCNT reprogramming in 30% (36 of 120) of Prm1-positive cells (Figure 1L). H3K9me3 was not longer detectable in fully condensed nuclei totally devoid of H3K9me3.

**Dynamics of Prm1 Incorporation**

Prm1 assembly on DNA of somatic cells leads to an overlapping of nuclear morphology like the one found in elongating spermatids.
spermatids (Figures 1G–1I). Prm1 appears in foci scattered throughout the nucleus 20-hr post-transfection (Figure 2B) and fully coalescences 48 hr later in an elongated structure (Table 1). The final outcome is an elongated and flattened nucleus, very much similar to the spermatooza’s, but larger, due to the diploid DNA content (Figure 2I). The degree of nuclear compaction in protaminized somatic cells approaches that of spermatooza when observed by transmission electron microscopy (TEM) (Figures 2F–2G).

Histone hyperacetylation opens chromatin structure in spermatids and is a pre-requisite for histone/Prm replacement. Accordingly, transfected cells treated with TSA incorporated more and faster Prm1 than control without TSA (at 16- to 20-hr post-transfection: TSA 47.8% [33 of 69]; without TSA 25.8% [38 of 147], p = 0.0018; at 40–48 hr: TSA 83.3% [50 of 60]; without TSA 47.8% [33 of 69]; p = 0.0010; Table S1).

Physiologically, the massive DNA compaction proper of spermatooza is achieved through the induction of double strand DNA breaks and repair (Rathke et al., 2014). Therefore, we tested whether the same would apply to our forced conversion of somatic chromatin to a protaminized structure. We analyzed via immunofluorescence the nuclei for the presence of the histone variant γH2A.X (a marker of double-strand DNA breaks) around the Prm1 condensed foci, but no positive γH2A.X signal was detected (H2A.X positive: CTR 10.2% [6 of 59]; CTR + [UV irradiated] 63.2% [48 of 76]; Prm1-RFP 10% [6 of 60]; Prm1-RFP/TSA 12.5% [8 of 64]; Figure 2J). A comet assay also excluded the presence of DNA fragmentation in fully protaminized fibroblasts (Figure S3).

Protaminized cells showed signs of degeneration on the third day after transfection, likely a consequence of the global transcription shut down resulting from chromatin compaction (Figure 2C).

**DISCUSSION**

Here, we have found that ectopic expression of Prm remodels the interphase chromatin of somatic cells, leading to a nuclear compaction strikingly similar to that of elongated spermatids. The absence of γH2AX immune localization was surprising, for it is hardly conceivable a genome-wide protaminization without torsional stress alleviation through DNA double-strand breaks (Laberge and Boissonneault, 2005). Probably, other DNA repair enzymes not tested here might be involved; accordingly, γH2AX has not been detected during chromatin remodeling in human spermatids (De Vries et al., 2012). Another possibility is that the histone variant γH2AX might have been evicted by Prm binding; however, a comet assay of fully protaminized cells excluded major DNA damage (Figure S3).

The ChiP-seq dataset demonstrated the effective binding of Prm1 to DNA on 42 DNA binding sites on 10 out of 27 chromosomes (2n = 54 in sheep) (Figure 2J; Table S1). Binding occurred in 28 gene-rich domains—14 (50%) genic and 14 (50%) intergenic—while the other 14 were classified as scaffold (Table S1). Early nuclear remodeling in round human spermatids is marked by the appearance of a single doughnut-like structure. The doughnut is the morphological expression of nucleosome disassembly, for nucleosome-destabilizing histones (H4K8ac and H4K16ac, H3K9me2) co-localize with it (De Vries et al., 2012). These findings suggest that genome remodeling starts

at a defined site in the genome and spreads in a spatially regulated manner, ending up with the nuclear compaction found universally in male gametes. Live imaging of the histone-to-Prm transition could be a powerful tool to test this hypothesis, but it is only available in *Drosophila* (Awe and Renkawitz-Pohl, 2010), not in mice or man. Also, currently unavailable are in vitro models to monitor the whole process of spermatogenesis.

The protaminization of somatic cells might provide unique insights on the early steps of chromatin remodeling, allowing the identification of the very first genome domain(s) binding with Prm. The simplified model for nucleosome-to-Prm exchange reported here might also add to the ongoing debate on nucleosomal retention in male gametes (Samans et al., 2014; Weiner et al., 2015). It would be interesting to map on a genome-wide scale, the Prm-histones’ footprints on Prm1-expressing somatic cells, to see whether the pattern described in spermatozoa is conserved.

Our findings also impact SCNT (Wilmut et al., 1997). SCNT is a promising technology whose full implementation is on hold because of its low efficiency. Recent successes on human embryonic stem cells isolated from somatic cell-derived cloned embryos have boosted interest in SCNT (Tachibana et al., 2013; Chung et al., 2014). This renewed interest in SCNT goes along with targeted nuclear reprogramming strategies, like

(C) SCNT of fibroblast transfected with pPrm1-RFP. (a) Picture represents 20 μm. Prm1 is red, and nucleus is blue.

(D) Table 2. Quality of blastocysts is as follows: IVF, in vitro fertilized; NT Prm1, protaminized; pPrm1-RFP, pPrm1, or pRFP by Lipofectamine 2000 (Invitrogen), according to the manufacturer’s instructions. At 4-hr post-transfection, medium was changed for DMEM containing 5 nM TSA or control (no TSA), and SAFs were cultured for additional 16, 20, 40, 48 hr. For cell-cycle analysis, SAFs before transfection were starved with 0.5% FBS for 5 days.

**Histone Exchange Visualization**

To visualize histone-to-Prm exchange, SAFs were first transfected with construct expressed GFP fused to histone 2B using BactMam 2.0 Technology (C10594, Celllight Histone 2B-GFP, BacMam 2.0, Life Technologies) according to the manufacturer’s instructions and then with pPrm1-RFP, as described above. Histone 2B-GFP and Prm1-RFP behavior in live cells using fluorescent imaging were observed.

**TEM**

Cells were fixed in glutaraldehyde (2.5% in 0.1 M cacodylate buffer [pH 7.4]) for 24 hr. After washing in ddH2O, cells were post-fixed in 2% OsO4 in ddH2O for 2 hr. Next, cells were dehydrated through a graded series of ethanol solutions (30%, 10 min; 50%; 15 min; 70%; 24; 80%, 10 min; 96%, 10 min; 100%, 10 min; acetone, twice for 15 min) and were infiltrated with graded concentrations of Epoxy 812 Resin (EPON) resin in 100% acetone (1:3, 20 min; 1:1, 24 hr; 3:1, 2 hr), infused twice for 1 hr in pure EPON resin, and polymerized at 65°C for 24 hr. Next, 60-nm sections were prepared and examined using a LEO 912AB electron microscope. Images were captured using a Slow Scan CCD camera (Proscanie) and EsVision Pro 3.2 software (Soft Imaging Systems GmbH).

**Immunostaining**

-\(\gamma\)H2A.X and Trimethyl-Histone H3

Cells were fixed in paraformaldehyde (PFA) for 15 min, permeabilized with 0.1% (v/v) Triton X-100 in PBS or 30 or 20 min, and blocked (0.1% BSA/0.05% Tween 20 [v/v] in PBS) for 1 hr at room temperature (RT). Then cells were incubated with the anti-phospho-Histone H2A.X (Ser139) (\(\gamma\)H2A.X) mouse antibody (1:100) (05-636, Millipore) at RT for 2 hr or anti-Trimethyl-Histone H3 (Lys9) rabbit antibody (1:200) (07-523, Millipore) at 4°C overnight. Subsequently, the secondary anti-mouse IgG-FITC (1:100) or anti-rabbit IgG-FITC (1:200) was added for 2 hr or 50 min at RT. Nuclei were counterstained with 5 μg/ml of 4',6-diamidino-2-phenylindole (DAPI).

**ChIP-seq Assay**

**Chromatin Immunoprecipitation**

ChIP assay was performed with the EZ-Magna ChIP kit (Millipore) according to the manufacturer’s instructions with minor modification. Protein and DNA complexes from pPrm1-RFP-transfected cells were cross-linked with 0.5% formaldehyde for 10 min at RT. Sonication was done in nuclear buffer (six 30-s pulses, power setting 10 and six 30-s pulses, power setting 15 in ice with 50-s rest between pulses; Bandelin Sonopuls). Soluble chromatin was immunoprecipitated with anti-RFP antibody (Evrogen) directly conjugated with Magnetic Protein A beads. DNA and protein immune complexes were eluted and reverse cross-linked, and then DNA was extracted using a spin filter column. DNA obtained from pRFP, pPR1-RFP, and Input were subjected to ChIP sequencing.

**ChIP Sequencing**

Next-generation sequencing experiments, comprising samples quality control, were performed. Indexed libraries were prepared from 10 ng/each ChIP DNA
with TruSeq ChIP Sample Prep Kit (Illumina) according to the manufacturer’s instructions (for details see Supplemental Experimental Procedures).

**NT**

In vitro embryos production was adapted from those previously described (Ptak et al., 2002). Oocytes manipulation was carried out with a piezo-driven enucleation and injection pipette (PiezoXpert), as previously described. Enucleate oocytes were injected with a nucleus, either from CTR or a Prm1-RFP fibroblasts suspended in PBS with 6% polyvinylpyrrolidone (Sigma-Aldrich). Activation and culture of reconstructed oocytes were processed as described (Ptak et al., 2002; Iuso et al., 2013d). Qualities of obtained blastocysts were performed as described by Iuso et al. (2013b).

**TH2B Immunostaining on Pronuclear Stage Embryos**

The zona pellucida of embryos at pronuclear stage (10- to 12-hr post-activation) was removed by incubation in 0.5% (w/v) pronase and acid Tyrode’s solution for 30 s. Then embryos were fixed in 4% PFA for 15 min and subjected to immunofluorescence analysis as described in Torres-Padilla et al. (2006) with the rabbit anti-TH2B antibody (1:700, ab23813 Abcam). Finally, zygotes were mounted with Vectorshield mounting medium with 5 μg/ml of DAPI.

**Statistical Analyses**

The Fisher’s exact were used to compare quantitative data on nuclear incorporation of Pm1 and in vitro development. Statistical analyses were performed using GraphPad Prism 5.0 software.

**SUPPLEMENTAL INFORMATION**

Supplemental information includes Supplemental Experimental Procedures, three figures, and two tables and can be found with this article online at http://dx.doi.org/10.1016/j.celrep.2015.10.066.

**AUTHOR CONTRIBUTIONS**

P.L., D.I., M.C., and S.K. conceived the experiments. D.I. and M.C. performed all NT and characterization work of Pm1 cells, and M.C. performed the vector integration and transfection. F.Z. did the embryological work. G.P. supervised the embryological work and discussed the results. P.T. and A.F. performed the molecular work. S.H. cloned Prm. T.B., S.C., and H.S. performed TH2B immunofluorescence analysis as described in Torres-Padilla et al. (2006) with the rabbit anti-TH2B antibody (1:700, ab23813 Abcam). Finally, zygotes were mounted with Vectorshield mounting medium with 5 μg/ml of DAPI.
